FOREWORD

This report was prepared by Lessells and Associates, Inc., Boston, Massachusetts, under U. S. Air Force Contract No. AF 33(616)-2324, Project No. 6-(1-3346), "Propeller blades." The contract was administered under 'he direction of the Propeller Laboratory, Wright Air Developmen. Jenter, with Mr. M. W. Baldwin acting as project engineer. The author wishes to acknowledge the assistance of Mr. E. L. Rich who conducted many of the tests and contributed to the analysis of results.

AMSTRACT

This report is the third in a series covering work performed under Contract No. AF33(61's)-2324 during the period from 1 February 1954 to 30 November 1956. The current report covers the period from 1 September 1953 dirough 30 November 1956. The object of the investigation was to determine any benefits of shot peening as a means of protecting directly propelled blades against the reduction of fatigue strength crisins from service damage. This report covers additional fatigue tested supplementing those reported in Part 2 and including more severe sumage than previously tested. It also covers tests conducted for the purpose of enabling estimates to be made of the limitations imposed by distortion in the passing of actual parts.

The results further substantiate the bencits of shot peening as a barrier to the detrimental effects of service damage. Tests on SAE 4340 steel specimens indicate that the benefits increase with increasing haroness of steel. Empirical relations derived from the distortion tests are also included. These relations allow prediction of the curvature to be expected from the peening of flat plates under any practical peening conditions.

I. INTRODUCTION

The work reported in this paper is directed at increased knowledge of the beneficial effects of shot peening in the prevention of fatigue failure in aircraft propeller blades. It has been hypothesized that the introduction of surface layer of compressive residual stress might impede the formation and growth of cracks through points subjected to damage in service. Experiments supporting this hypothesis were carried out and are reported in WADC TR 55-56, Parts 1 and 2. These reports cover the background material as well as the complete details of procedures involved in shot peening, measurement of residual peening stresses, fatigue tests, etc. These details will not be repeated in this report except in cases where they may have been altered in the more recent work. Material properties of the SAE 4340 steel and 76S-T6 aluminum are identical to those previously reported.

The current phase of the investigation involves 1) in igue tests supplementing those previously reported and 2) a study directed at the prediction of the distortion which would accompany the shot peening of propeller blades. The latter phase is of interest because of the obvious limitations arising with maximum shot size and/or intensity and minimum blade thicknesses, especially as regards hollow blades. The studies of distortion discussed here are limited to flat plates of various thicknesses peened on one side only in order that the basic responses and parameters may be established.

II. FATIGUE TESTS

LIGHT DAMAGE

Additional tests covering the case of light damage on 45° iteel were conducted in order to provide supplementary data. It will be recalled that the light damage, as described in WADC TR 55-56, Part 2, is produced by fragments of broken glass striking the specimen. The supplementary data were desired in order to movide more tests for more accurate statistical analysis and to provide a check on the Prot slope, which previously was taken as the value reported in WADC TR 52-234. Table I is an uniting of the tast program involving the light damage. A few Sand tests were included for the purpose of checking the endurance white indicated by the Prot method. Table 2 outlines the S-N test conditions. Complete data on all fatigue test specimens are given in Appendix I. The failure stresses indicated have been corrected for going depth.

681-692	260,000		50	Light

This correction is based on the reduction in nominal stress in a bending specimen by virtue of the depth from the original surface at which the failure originates. This depth is determined by breaking open the specimen and examining microscopically to discover the origin of failure. In the case of the light damage the correction is usually quite small, such that any exports in this principle of reducing the stress by the ratio of failure depth to half the thickness is quite small. In the case of very deep gouges, as discussed later, errors in this correction may be greater.

Figures 1 through 3 give the results of tests run for the purpose of checking the Prot slope. Previous data reported in WADC TR 55-56, Part 2 are included in these curves as well as in all the other applicable curves of light damage. Applicable values of the S-N results are also included in the figures. Two Prot slopes are drawn where the data permit. One slope is that reported in WADC TR 52-234, used in previous reports under this contract. second is that derived from data obtained during the phase reported The second slope is greater, indicating lower endurance limits than the first. Some question arises as to the proper value of rate of stress increase to be used in the case of notched or damaged specimens. The rates plotted here are the nominal rate at the It can be argued that the rate should be reduced to that determined by the nominal stress at the depth of failure. This would in general indicate higher endurance limits, although the change would be slight for shallow notches. On the other hand, it can be argued that the actual failure stress at the root of a notch is the product of the nominal stress and a stress concentration factor. If this were also applied to the stress rate, higher rates would be indicated. Which of these effects is the more realistic is unknown at the present time. It would thus appear that a basic deficiency exists in the Prot method when applied to notched specimens, except in cases wherein a nominal stress used for comparative purposes is adequate. Fortunately, the current investigation is satisfactorily covered by the latter situation in that comparative results are adequate, even though precise knowledge of the actual endurance limits is not obtained. With this in mind and in order to compare previous results with current results, the original slope as reported in WADC TR 52-234 has been used in calculating endurance limits. All conclusions are based on this Prot slope. It should be noted in passing that when the data are plotted using both the nominal surface stress and the nominal surface rate of stress increase, the slope agrees almost exactly with that reported in WADC TR 52-234.

Figures 4 through 6 give the results of all other Prot tests involving either no damage or light damage. These tests were run at the nominal rate of increase of .04 psi per cycle and endurance limits were determined by resorting to the slope, as described above. Figures 7 through 10 show the results of S-N tests. An overall summary of the average endurance limits indicated by the Prot and S-N tests for the cases of either no damage or light damage

Prot and S-Ntests for the cases of either no damage or light damage is given in Figure 11. As stated before, the results are averages which include the previous applicable data reported in WADC TR 55-56. Part 2.

Figure 12 shows the percent variation in failure stress vs. the ratio of depth of compression to depth of damage for the case of light damage.

Figure 13 is a photograph of the two surfaces of a failure which originated at a glass-like inclusion of spherical form. Figure 14 shows a typical sub-surface failure in which the presence of foreign matter was not definitely established. The "fish eye" which is typical of sub-surface fatigue failure is evident in the photographs.

HEAVY DAMAGE

Tests were also included in the current phase of the program in which heavier damage than used previously was imposed on the test specimens. This damage was produced by the same glass missile as described previously except that the glass was not fractured prior to con.act with the specimen. Each specimen was subjected to a single gouge. In some cases the glass missile fractured very shortly after initial contact with the specimen producing a spray pattern of relatively light damage over the surface but with frequently a moderately deep groove over a distance of about 1/2 in. across the specimen. In other cases the glass missile did not fracture until it had traversed approximately 1/2 in. of the specimen, This resulted in a very shar; clean single groove varying in depth from zero at the point of contact to: maximum at the point of eventual fracture. Attempts were made to measure the radius of curvature at the bottom of the groove. This radius could not be precisely uetermined but it is less than, 0001 in. Considerable cold work was evident along the sides of the grooves. The groove usually ended rather abruptly at the point of eventual fracture of the glass, this end being filled with remaining fragments of glass. There deep gouges were obtained with all three hardnesses of the 4340 steel although the percentage of deep gouges decreased with increasing specimen hardness. An occasional deep gouge was found even at the highest hardness of R 52.

For purposes of analysis this heavy damage was divided into two categories according to whether or not the excessively deep louges were formed. In all cases the failure stresses were corrected for depth by reducing the stress from the surface in a linear fashion by the ratio of depth of failure origin to semi-thickness of the bar. With the excessively deep gouges this procedure may be subject to some error. The nominal stress at the bottom of one of these deep gouges, as calculated in this fashion, is as little as one-

half the nominal stress at the surface of the bar. No correction was made for the reduction in section modulus due to the existence of the gouge. The inaccuracy is not considered serious however, inasmuch as the value of tests on the excessively deep gouges is very small. These gouges are such that rejection of a propeller blade containing such gouge would be unquestioned. Further, they are of depths far greater than could be benefited by any reasonable peening treatment. Consequently, value is placed only on these beavy gouges which are not of excessive depth, that is of depth exceeding approximately .016 in. Thus, specimens containing these heavy gouges of .016 in. depth or greater are not included in the analysis of results, although the failure data are given and the points are plotted.

Table 3 is an outline of the test program involving the heavy damage. Appendix I includes data on the specimens containing damage as well as those specimens previously mentioned.

Figures 15 through 24 give the results of Prot tests on the heavily damaged specimens of various hardnesses and peening treatments. Figure 25 gives the average results of these tests for the heavily damaged specimens. It can be seen that the benefits of peening are apparent even with the moderately heavy damage. Figure 26 shows the percent variation in failure stress vs. the ratio of depth of compression to depth of damage for the case of heavy damage.

III. DISTORTION

RESIDUAL STRESS AND CURVATURE

Because of the fact that the residual stresses produced by peening are a result of plastic and elastic strain, it is apparent that some dimensional change must necessarily accompany this treatment. The degree of this dimensional change is of course affected by the geometry of the part and the severity of peening. The propeller blade, being essentially a thin plate with some superimposed twist, might therefore be distorted to a sizeable degree by a heavy peening operation. It is essential that some knowledge of the distortion as a function of peening condition be obtained. This knowledge would enable prediction of the limits of peening in an actual case.

The study of distortion has been confined to flat plates peened on one side only. This case allows study of the fundamentals involved in distortion and permits expression of some of the factors affecting the distortion such as hardness, thickness, etc. The extension of data obtained from these simple tests would involve consideration of the particular geometry of interest.

In studying dictortion, SAE 2540 steel specimens of varying thickness were peased under a variety of conditions. The result—
ing curvatures and residual stresses were evaluated. These data were then assembled in order to determine empirically the behaviour in distortion of the various thicknesses. This knowledge was then extended analytically to include the various hardnesses of steel as well as the single aluminum alloy under consideration. A listing of the residual stress specimens tested and the peening conditions involved is given in Table 4. All tests were undertaken at high shot coverage and using steel of hardness R 44. A constant shot flow rate (10 lb/min) and a fixed air pressure (50 psi) were used throughout the tests. Specimen size and shape were identical to those reported in Part 1 of WADC TR 55-56.

Since the distortion is produced primarily by the compressive stress from the peening operation, it seems apparent that the magnitude and depth of this compressive stress would be the most important factors in analyzing distortion. The maximum value of the stress, the depth, and the shape of the stress curve are involved in the force producing the distortion. These factors can be lumped together in terms of the compressive residual stress area which is the integral of stress times depth. This residual stress area then represents the force per unit width of flat specimen which is acting to produce extension and bending. Bending is the more predominant factor in the case of a flat specimen peened on one side only. If it is assumed that similar peening treatments produce the same compressive residual stress area on different thicknesses of identical

material should be possible to calculate the curvature which would be a seed on each of these thicknesses. The energy of compressive steem usi be offset by equal amounts of energy in the remainder of specimen. Further, for equilibrium the compressive and tensile forces and moments must balance. Therefore, it should be possible to calculate approximately the entire residual stress distribution and the resulting specimen curvature knowing the characteristics of the compressive residual stress.

The test program was designed to study these affects as well as to detect relations between the potential energy of the specimen, the potential energy of an Almen strip peened simultaneously with the specimen, and the kinetic energy of the shot stream.

DISTORTION TEST RESULTS

The residual stress results for the various distortion test specimens are plotted in Figures 41 through 74 in Appendix II. The data from which these results are calculated are presented in Appendix III. As stated previously, the various tests involved only a single hardness of steel. These data are combined in the succeeding discussion with previous data on 1/4—in. thick specimens of varying hardnesses of steel and of aluminum 765-T6.

Figure 27 indicates that the compressive residual stress area is unaffected by specimen thickness above a thickness of 1/8 in. for the peening conditions tested. Since for a given hardness of steel the maximum value of compressive stress is nearly constant and is at or near the surface, then a variation in compressive residual stress area is essentially directly proportional to the depth of compression. Thus, the depth of compression becomes a measure of distortion for specimens of constant hardness. Figure 28 shows the curvature vs. the depth of compressive layer for the various thicknesses of R 42 material tested. Observation of this figure revuals a definite relation of curvature to thickness of specimen. It develops that the square of the thickness is the proportionality constant. Figure 29 is a plot of Ct² (curvature times the thickness squared) vs. depth of compression, it can be seen that, when plotted with this parameter, all thicknesses are represented on the name curve. Figure 29 also includes the average values of Ct2 for each of the other hardnesses of steel and of aluminum. It should be noted that the latter values are based on only one inicances, it being assumed here that the same relations will apply that apply to the Figures 30 through 32 show the curvature parameter Ct 2 plotted against the compressive residual stress areas for all hardnesses and shot conditions of steel. These three curves are essentially identical to each other. Figure 33 is the corresponding

FIGURE 27. EFFECT OF THICKNESS ON COMPRESSIVE RESIDUAL STRESS AREA

curve for aluminum and can be made to coincide with the curve for these steels by multiplying by the ratio of the elastic moduli, i. e., E_{St}/E_{Al} . These curves, when combined with the residual stress data given in WADC TR 55-56, Part 1, allow the determination of the specimen curvature to be expected from any peening condition.

It is also of interest to relate these variables to the Almen arc height observed during peening, since the latter is the common method of determining the peening conditions. Consequently, Figures 34 and 35 have been included. These are plots of the various parameters against the Almen Carc height resulting from the peening. It will be noted that the slope of Ct² vs. Almen C increases at an Almen C value of approximately .008 in. This is attributed to the limitation observed in low thicknesses, as was shown in Figure 27, and is a result of increased stiffness as the thin strip develops transverse curvature.

Although the maximum value of compressive stress and depth are of primary interest, the peak value of tensile residual stress immediately below the compressive layer may also be of interest in many cases. Figure 36 shows how this peak value changes with specimen thickness. It can be seen that the value of tensile stress increases as thickness decreases. This is reasonable as it is necessary to enable force and moment equilibrium to be maintained. In this connection Figure 37 shows the location of the neutral axis, that is the point at which the residual stress becomes zero after having reached its maximum value of tension. It can be seen that the position of the neutral axis is a function of thickness only, regardless of the peening conditions on a given material. The tests as shown were conducted only on R 42 material in which the maximum value of compressive stress is essentially constant.

A summary curve for all materials tested results from the inclusion (in the parameter Ct²) of the modulus and the maximum compressive stress for each specimen. Figure 38 is a plot of the

parameter Ct2 E vs. the depth of compression for all cases con-

sidered; that is for all materials, coverages, shot sizes, air pressures, and thicks sees tested. Thus, given the dimensions of the piece to be thereford and knowing either the maximum compressive stress resulting them peening of that hardness on the depth of compression resulting from the peening, it is possible to determine the distortion which would result. The depth of compression can be obtained from curves for the various materials and peening conditions as given in Part I. Because of the large number of data points available for Figure 35, only about 20% of the points have been plotted. Every fifth point was selected from a numerical listing of specimens.

FIGURE 34. DEPTH OF COMPRESSION VS.
ALMEN ARC HEIGHT

FIGURE 35. DISTORTION PARAMETER Vs. ALMEN "C"

FIGURE 36. RATIO OF MAXIMUM COMPRESSIVE STRESS TO MAXIMUM TENSILE STRESS

FIGURE 38. DISTORTION PARAMETER CORRECTED FOR MATERIAL PROPERTIES

It seems theoretically probable that a more universal curve relating compressive stress and depth to the kinetic energy of the shot, either the single shot or the total shot stream, could be obtained. This relation, however, has not yet been discovered. The depth of compression can however be related for each material and shot velocity. Figure 39 shows the ratio of depth of compression/shot diameter for R_c 42 material vs. the parameter L^3V^3 , where D is the shot diameter (in.) and V is the shot velocity (it/sec). The exact physical significance of this parameter is not clear. It would seem that the parameter D^3V^2 would be more representative of the kinetic energy of a single shot. A plot of this parameter, however, does not produce a smooth curve.

IV. MEASUREMENT OF SHOT VELOCITY

In order to correlate the results of these peening tests with shot peening as done on other equipment, it was deemed necessary to know the velocity of the shot. This was measured by means of high-speed flash photography. A high-intensity flash tube was placed in the rear of the peening cabinet. A viewing window was cut into the front of the cabinet such that the shot stream was silhouetted against the flash tube. A reference marker 1-in. long was placed adjacent to the shot stream. The flash tube was triggered by an oscillator operating either at 1800 or 2400 cps, depending on the particular run. The tube flashed 3 times, each flash being less intense than the previous one. The camera was placed at the viewing window and aimed at the flash tube with open shutter. film was subjected to a triple exposure with a known time between exposures. This resulted in a picture wherein individual shot could be identified at 3 locations with respect to the l-in, marker and with respect to the known time. This enabled the calculation of the velocity of shot.

Figure 40 shows the results of this test. It can be seen that the maximum velocity obtained is approximately 120 ft/sec. It can also be seen that the shot velocity is practically independent of shot lize. This may be partly due to the fact that the shot and air nozzle sizes were changed with the shot size in accordance with the schedule previously reported in Part 1. The values of shot velocity are somewhat lower than would be expected from a wheel-type machine. They are also somewhat lower than those reported by Coombs, Sherratt and Pope at the International Conference on Fatigue of Metals. London, 1956, but agree quite closely to some unpublished data taken on a similar cabinet.

HOISESAGMOD TO HTG3C RETEMBLIG TOHS

Figure 40 can be used to convert all values of air pressure previously reported to shot velocity, enabling results on other equipment to be compared with those reported from this project.

V. CONCLUSIONS

For the case of light damage, shot peening increased the fatigue strengths of SAE 4340 steel of hardnesses R_c 51, R_c 42 and R_c 52 by 19%, 53% and 86%, respectively. The optimum ratio of depth of compression to depth of damage is about five or greater, elthough considerable improvement in fatigue strength of R_c 42 and R_c 52 material is achieved at a ratio as low as two.

For the case of heavy damage, shot perning increased the fatigue strengths of SAE 4340 steel at hardnesses R_c31, R_c42 and R_c52 by 72%, 120%, and 133%, respectively. The figure for the R_c31 is based on an estimated fatigue strength for the unpeaned—damaged material. The optimum ratio of depth of compression to depth of damage is about five or greater, although considerable improvement in fatigue stringth was noted at a ratio as low as one

A check of the Prot slope resulted in a value which would indicate a lower endurance limit than would be indicated by WADC TR 52-234. When failure stresses and stress rates are not corrected for gouge depth, the slope is identical to that reported in WADC TR 52-234. S-N tests in general confirmed the lower values of endurance limit. The S-N tests showed considerable scatter, however, which is a natural result of scatter in the damaged specimens.

S-N tests on the barder steels failed to reveal definite fatigue strengths, a condition which has been noted by a few other investigators.

Empirical curves and parameters relating distortion of flat plates to peening conditions have been established. The parameter $\frac{Ct^2E}{e^{-2}}$, when plotted against the depth of compressive layer, appears to relate all peening conditions, thicknesses and materials tested.

The compressive residual stress conditions are essentially constant for thicknesses of 1/8 in. and above. On the lasis of a fewtests, the residual stress condition thanger below 1/8 in. thickness. For a given state of compressive stress in the region of the surface, the tensile stress beneath this layer increases with decreasing thickness.

FIGURE 40. SHOT VELOCITY VS. AIR PRESSURE

APPENDIX I

FATIGUE TEST SPECIMENS

The table on the following pages lists all fatigue specimens tested, together with the peening conditions, type of damage and failure stress for each. The maximum gouge depth refers to the deepest penetration of the gouge through which failure occurred. The gouge depth at failure refers to the depth at the nucleus of the fatigue crack.

APPENDIX II

RESIDUAL STRESS RESULTS

The following rages give the detailed residual stress distributions for specimens tested in connection with the study of distortion. Table 2 outlines the various test conditions from which these distributions resuited. Table 6 in Appendix III contains the data from which the stress distributions were calculated. A sample calculation was presented in WADC TR 55-56, Part 1.
